How to Avoid Singularity When Using Euler Angles?
Puneet Singla*, Daniele Mortari†, and John L. Junkins‡

In this paper, an algorithm is proposed to avoid singularity associated with the most famous minimum element attitude parametrization, Euler angle set. The proposed algorithm makes use of the method of sequential rotation to avoid singularity associated with Euler angle set. Further, a switching algorithm is also proposed to switch between different Euler angle sets to avoid the singularity while integrating the kinematic equations corresponding to Euler angles for spacecraft motion. The algorithm is numerically validated by simulation tests.

1 Introduction

Spacecraft attitude determination is the process of estimating the orientation of a spacecraft by making on-board observations of other celestial bodies or reference points, with respect to some reference frame. Attitude parameters are the set of coordinates that completely describes the orientation of the spacecraft with respect to a given reference frame, as for instance the inertial reference frame. Leonard Euler in 1775 has shown [1, 2] that the configuration of a rigid body can be fully defined by locating a cartesian set of coordinate fixed in rigid body (called body frame) relative to some inertial coordinate axes. Three parameters are needed to define the origin of body frame and another three parameters are needed to specify the orientation of body frame with respect to external inertial frame. That’s why, generally two or more co-ordinate systems are defined for attitude determination process: one on the vehicle body called the body frame and second is the inertial reference frame. For most problems, the reference frame is a non-moving an inertial frame fixed to the center of Earth. The projection of the body frame axes onto the image frame axes is given by

an orthogonal matrix \((C)\) called the Direction Cosine Matrix (DCM) or orientation matrix or attitude matrix. A large number of parameterizations\[3\] are discussed in the literature for attitude matrix. But Euler Angles (EA), Euler’s principal axis and angle, Euler-Rodrigues Symmetric Parameters (ERSP) or the quaternion, Rodrigues Parameters (RP), and Modified Rodrigues Parameters (MRP), are the most popular ones. The last three (ERSP, RP, MRP) are closely associated with Euler’s principal rotation theorem, namely that the most general angular position can be achieved with a single principal rotation about the principal axis. Every parametrization has its own advantages and disadvantages. The main properties of some classical parameterizations of attitude rotational matrix are listed in Table 1:

From Table 1, we can infer that all the minimal sets of parameterizations of attitude rotation matrix have some non-linearity associated with their differential kinematic equations and some kind of geometric singularity, except two the redundant set of parameterizations, one is attitude matrix and the other is the ERS. Both of them have linear and universally applicable differential kinematic equations (for that case that \(\vec{\omega}(t)\) is known). The attitude matrix has 6 redundant parameters whereas the quaternion has only one redundant parameter, which makes it more preferable, from several perspectives, to all the other representations of attitude.

However, the two main reasons that blessed the quaternion as king of attitude parametrization, namely the fact that subsequent rotations do not involve use of transcendental functions and the fact that all minimum parametrizations of attitude present a sin-
gularity, both of them appear to fall. The reason relies on the fact that the problem of avoiding the use of transcendental functions belongs to the era (up until very recently) when these functions were computed by series expansions or pade approximation, which is, indeed, computationally expensive while now they are much more efficiently evaluated by simple look-up tables.\textsuperscript{5} The second reason comes out from the capability of Shuster’s Method of Sequential Rotations\cite{4} (MSR) to avoid the un-avoidable singularity affecting all the minimum attitude parameter sets. Not only the original QUEST\cite{4} algorithm has taken advantage of the MSR technique, but also some recent attitude determination approaches, like ESOQ2\cite{5} and OLAE\cite{6}.

The attention to MSR has increased in applications, and also the complete theory of it has been developed\cite{7}. For these two reason MSR deserves more attention than has been given.

The basic idea of the method of sequential rotation lies in performing an artificial rotation $R$ of the $n$ observed directions $b_i$ or of the associated reference directions $r_i$. This, in general, would vary the value of computed attitude. If the original observed directions $b_i$ correspond to the attitude matrix $C$ and $R$ represents the sequential rotation matrix, then the computed attitude parameter set will correspond to the modified attitude matrix $CR^T$. Thus, if the original data set is such that the attitude estimation algorithm is singular, then the rotated data set can be defined in such a way that it is not singular. It looks very simple but a practical problem remains how to best learn when a particular attitude parameter set approaches a singularity at a particular instant and “how to get the original attitude parameter set?” In reference \cite{7}, this problem has been discussed in detail for Rodrigues and modified Rodrigues parameters. However, the process of sequential rotation does not work as well for Euler angle set, because the process of extracting the original Euler angles is very tedious and generally does not provide any simple, compact expressions. But there remains an immense interest in Robotics and spacecraft control problems to parameterize the attitude matrix in terms of Euler angle sets as they provide most easy to visualize geometric recipe to describe the motion of any object with respect to a reference frame.

In this paper, we present an efficient algorithm to estimate the spacecraft attitude in terms of non-singular Euler angle set. First, we present a procedure to detect the singular Euler angle set from vector observations only and then present an approach to estimate the non-singular Euler angle set from these vector observations by solving a Generalized Wahba Problem \cite{8}. Also, a procedure is presented in this paper that provides a rigorous linearization of attitude estimation problem, if three or more vector observations are available, and can be used as a starting estimate for any nonlinear estimation algorithm.

\textsuperscript{5}A look-up table technique consists of evaluating a function just by interpolation between two close pre-computed values. For instance, in MATLAB, only one floating point operation is required to evaluate $\sin x$. 

3
2 Euler Angle Sets

In this section, we list a procedure to find which Euler angle set is singular based upon vector observations. But before discussing the algorithm, we give a brief introduction to Euler angle sets.

Euler angles are the most commonly used sets of attitude parameters. They describe the attitude of reference frame relative to inertial frame by three successive rotation (Euler) angles \((\theta_1, \theta_2, \theta_3)\) about the body fixed axes. The order of the axes about which the reference frame is rotated is important here. These three successive rotations provide an instantaneous geometrical recipe for a reference frame undergoing a general motion, i.e., the Euler angles are generally time varying.

Since all rotations are performed about the orthogonal axes of the body reference frame, we define \(M_i = \exp \left( -[\tilde{e}_i] \theta_i \right) \) as an elementary rotation matrix about the \(e_i\)-body axis. Here, \([\tilde{e}_i]\) represents the skew-symmetric cross product matrix given by the following expression:

\[
[\tilde{a}] = \begin{bmatrix}
0 & -a_3 & a_2 \\
a_3 & 0 & -a_1 \\
-a_2 & a_1 & 0
\end{bmatrix} \tag{1}
\]

From the expression for \(M_i = \exp \left( -[\tilde{e}_i] \theta_i \right)\), we can construct the following three elementary rotation matrices:

\[
M_1(\theta) = \begin{bmatrix}
1 & 0 & 0 \\
0 & \cos \theta & \sin \theta \\
0 & -\sin \theta & \cos \theta
\end{bmatrix} \tag{2}
\]

\[
M_2(\theta) = \begin{bmatrix}
\cos \theta & 0 & -\sin \theta \\
0 & 1 & 0 \\
\sin \theta & 0 & \cos \theta
\end{bmatrix} \tag{3}
\]

\[
M_3(\theta) = \begin{bmatrix}
\cos \theta & \sin \theta & 0 \\
-\sin \theta & \cos \theta & 0 \\
0 & 0 & 1
\end{bmatrix} \tag{4}
\]

if \(i, j,\) and \(k,\) indicate the coordinate axes about which each subsequent rotation is performed, that is, they can be any integer from 1-3, provided that \(i \neq j\) and \(j \neq k,\) are satisfied, then the resultant direction cosine matrix can be written as

\[
C_{ijk}(\theta_1, \theta_2, \theta_3) = M_k(\theta_3) M_j(\theta_2) M_i(\theta_1) \tag{5}
\]

In this way it is possible to define twelve sequences of Euler angles, associated with 12 representations of the attitude matrix, denoted by \(C_{ijk}.\) Accordingly with the chosen Euler angle sequence, we may distinguish the “symmetric set” \(C_{iji}\) (when first and last rotations occur about the same axis, and the “asymmetric sets” \(C_{ijk}\) with \(i \neq j \neq k,\) when all the three rotations occur about three distinct axes.
The Euler angle sets are the classical minimum parameter attitude, therefore they all have the disadvantage of being singular at either \( \theta_2 = 0, \pi \) or \( \theta_2 = \pm \frac{\pi}{2} \), but they all are easy to visualize which makes them popular for many attitude determination problems. For the asymmetric Euler angle sets \( \theta_2 = \pm \frac{\pi}{2} \) results in geometric singularity. For the symmetric Euler angle sets \( \theta_2 = 0 \) or \( \theta_2 = \pm \frac{\pi}{2} \) radians. We mention that all Euler angle sets encounter singularity only for \( \theta_2 = \pm \alpha \pi \) or \( \theta_2 = \pm \alpha \frac{\pi}{2} \), where \( \alpha \) is any integer (\( \alpha = 0, 1, 2, \ldots \)). This geometric singularity further induces the singularity in the corresponding Euler angle kinematic differential equations.

It is a fundamental topological fact that singularities can never be eliminated in any 3-dimensional representation of orientation. But we can avoid this singularity by describing the attitude at a particular instant by the Euler angle set which is farthest away from singularity. In this paper, we present an algorithm to switch between different sets of Euler angles to avoid this singularity and we can remain approximately 90° removed from the singularity.

3 How to Detect Singularity?

In the previous section, we have mentioned that the singularity in all “symmetric sets” \((i-j-i)\), of Euler angle corresponds to \( \theta_2 = 0 \) or \( \theta_2 = \pm \pi \) which further correspond to elementary rotation matrix \( M_j = I_{3 \times 3} \). Geometrically, this singularity corresponds to rotation about axis \( e_i \) by an angle \( \theta_1 + \theta_3 \). Further, if we look at the elements of the attitude matrix then this singularity can be described by the diagonal element, \( C_{ii} \) being \( \pm 1 \). Therefore, for a general symmetric Euler angle set \( i-j-i \) the singularity \( \theta_2 = 0, \pm \pi \) corresponds to \( C_{ii} = \pm 1 \). That is why none of the symmetric Euler angle sets can be determined uniquely the identity rotation i.e. \( C = I \).

Similarly, in case of “asymmetric” Euler angle set, “\( i-j-k \)” \((i \neq j \neq k)\), the singularity corresponding to \( \theta_2 = \pm \frac{\pi}{2} \) that is described by the following expression for elementary rotation matrix \( M_j \):

\[
M_j = exp(\mp [\hat{e}_j] \frac{\pi}{2})
\]

Using Rodrigues’ formula[3], we can rewrite the following expression for \( M_j \):

\[
M_j = I \pm [\hat{e}_j]
\]
It should be noticed that $j^{th}$ row of matrix, $[\tilde{e}_j]$, is equal to zero due to the fact that $e_j$ is a $3 \times 1$ unit vector with only $j^{th}$ element being non-zero. Further, keeping in mind the structure of the elementary rotation matrices $M_i$ and $M_k$, we can easily show that the $k^{th}$ row of attitude matrix $C_{ijk} = M_k M_j M_i$ is equal to $\pm e_i^T$, and $i^{th}$ column is equal to $\pm e_k$, where, $k \neq i$. For example, the attitude matrix for Euler angle set 3-2-1 is given by the following expression:

$$C_{321} = \begin{bmatrix}
c\theta_2 c\theta_1 & c\theta_2 s\theta_1 & -s\theta_2 \\
s\theta_3 s\theta_2 c\theta_1 - c\theta_3 s\theta_1 & s\theta_3 s\theta_2 s\theta_1 + c\theta_3 c\theta_1 & s\theta_3 c\theta_2 \\
c\theta_3 s\theta_2 c\theta_1 + s\theta_3 s\theta_1 & c\theta_3 s\theta_2 s\theta_1 - s\theta_3 c\theta_1 & c\theta_3 c\theta_2
\end{bmatrix} \quad (9)$$

In above written expression for $C_{321}$, it is easier to check that when $\theta_2 = \pm \frac{\pi}{2}$, the $1^{st}$ row equals to $-e_1^T$ and $3^{rd}$ column is equal to $e_1$.

Therefore, we can state following theorem to capture the singularity condition for a general Euler angle set:

**Singularity Condition.** If “$i$-$j$-$k$” denotes the given Euler angle sequence then it is singular iff the $k^{th}$ row of attitude matrix $C$ is equal to $\pm e_i^T$ and the $i^{th}$ column of the attitude matrix is equal to $\pm e_k$. Further, if $b$ and $r$ represents the body frame and inertial frame reference vector observations then the “$i$-$j$-$k$” Euler angle sequence is singular iff the $r_i$ component of inertial reference vector $r$ is equal to the $b_k$ component of the body frame reference vector $b$.

**Proof.** The proof of the first part of this theorem follows from the discussion in last section while the proof of second part follows from the fact that $b = Cr$. □

As a consequence of this theorem and the fact that the attitude matrix, $C$, is an orthonormal matrix, the singularity condition for “$i$-$j$-$k$” Euler angle set can be described by $C_{ki}$ element of the attitude matrix, $C$, being $\pm 1$. Table 2 lists all the singular Euler angle sets when $C_{ij} = \pm 1$.

### 4 How to Avoid Singularity

It is a fundamental topological fact that singularities can never be eliminated in any 3-dimensional representation of orientation. However, in this section, we discuss two approaches to avoid the singularity in any Euler angle sequence “$i$-$j$-$k$”.

The first approach is based upon the method of Sequential rotations [7] as discussed in section 1. According to MSR, the singularity in any minimal parametrization of attitude can be avoided by artificially composing the true attitude matrix, $C$ with a known rotation matrix, $R$. If the true attitude matrix $C$, the artificial sequential
rotation matrix $R$, and the computed attitude matrix $C_R$ correspond to the Euler angles $\Theta$, $\Phi$, and $\Theta_R$, respectively, then the problem of finding the original Euler angle vector corresponds to find $\Theta$ with $\Phi$ and $\Theta_R$ assigned. We mention that this process is very tedious and generally do not provide any simple, compact expression [9]. However, for the case when the Euler angle set is symmetric, then we can describe $\Theta$ in terms of $\Phi$ and $\Theta_R$ using spherical geometry relationships [9, 10]:

$$\Theta_1 = -\Phi_3 + \tan^{-1}\left(\frac{\sin \Phi_2 \sin \Theta_R \sin (\Theta_R - \Phi_1)}{\cos \Phi_2 \cos \Theta_2 - \cos \Theta_R}\right)$$

$$\Theta_2 = \cos^{-1}\left(\cos \Phi_2 \cos \Theta_R + \sin \Phi_2 \sin \Theta_R \cos (\Theta_R - \Phi_1)\right)$$

$$\Theta_3 = \Theta_R - \tan^{-1}\left(\frac{\sin \Phi_2 \sin \Theta_R \sin (\Theta_R - \Phi_1)}{\cos \Phi_2 - \cos \Theta_R \cos \Theta_2}\right)$$

But, unfortunately, for the case of “asymmetric” Euler angle sets, the expressions are much more complicated. However, if only the actual attitude matrix is of interest then MSR provides a very good mechanism to avoid singularity. Apparently, the method of Sequential rotation does not add a useful mechanism to avoid the singularity while integrating the Euler angle kinematic equations.

In the second approach, the fact that elements of direction cosine matrix $C$ are transcendental functions of Euler angles and therefore $C_{ij}$ lies between $-1$ and $1$ i.e. $\|C_{ij}\| \leq 1$, is used. For instance, Fig. 1 shows the plot of non-diagonal element $C_{ij}$ vs $\theta_2$ for “asymmetric Euler angle” set “$j$-$k$-$i$” and figure 2 shows the plot of diagonal element $C_{ii}$ vs $\theta_2$ for “symmetric” Euler angle set “$i$-$k$-$i$”. The red lines in the figures corresponds to the singular points, $C_{ij} = \pm 1$, while the green lines corresponds to the points farthest away from singularity. From figure 1, it is clear that an “asymmetric”
Euler angle set “j-k-i” will be farthest away from singularity if $\theta_2 = 0, \pm \pi$ i.e. $C_{ij} = 0$. Similarly from figure 2, we can conclude that a “symmetric” Euler angle set “i-k-i” will be farthest away from singularity if $C_{ii} = 0$ i.e. $\theta_2 = \pm \frac{\pi}{2}$.

Now, that means we should choose Euler angle set “3-2-1” if element $C_{13}$ of attitude matrix, $C$, is closest to zero at a particular instant of time. From equation (9), it is clear that it will happen only if $\theta_2 \approx 0, \pm \pi$. Further, from equation (9), we can see that this situation also corresponds to elements $C_{11}$, $C_{12}$, $C_{23}$ and $C_{33}$ being equal to $\pm 1$. From table 2, we can conclude that this corresponds to Euler angle sets 1-2-1, 1-3-1, 2-3-1, 3-1-2, 3-1-3, and 3-2-3, being singular. Table 3 lists all the Euler angle sets which best describes the attitude when $C_{ij} = \pm 1$.

From table 3, it is clear that more than one Euler angle set are farthest away from singularity whenever a particular Euler angle set approaches singularity. In case of “asymmetric” Euler angle sets the singularity can be avoided by either switching to another “asymmetric” or “symmetric” Euler angle set however, in case of “symmetric” Euler angle set the singularity can not be avoided by just switching to another ”symmetric” Euler angle set. In other words, the “symmetric” Euler angle sets can not be used to represent all possible attitude matrices. For example the identity rotation can not be parameterized by any “symmetric” Euler angle set. Therefore, if our purpose is just to avoid singularity, then we need to switch between an “asymmetric” and a “symmetric” or two “asymmetric” Euler angle sets but, if we want to make sure

</table>
that at every instant we use the Euler angle set that is farthest away from singularity, then we do need to switch between all the twelve Euler angle sets. For example, the singularity for 3-2-1 Euler angle set can be avoided by either switching to 1-2-3 or 3-1-3 Euler angle set and similarly, the singularity in the case of 1-2-3 or 3-1-3 Euler angle sets can be avoided by switching to 3-2-1 Euler angle set. Finally, we mention that switching between different Euler angle sets is also useful in integrating the corresponding Kinematic equations where the method of sequential rotation is not very useful. However, the easiest way to avoid singularity for preferred Euler angle set, is to adopt a “temporary inertial frame” approximately 90° away from the singularity and just revise the temporary inertial frame every time a singularity is approached.

5 Euler Angle Estimation

Due to various reasons discussed in section 1, there is an immense interest in parameterizing the attitude matrix in terms of a non-singular Euler angles set. In this section, we present an efficient algorithm to estimate the non-singular Euler angle set from given set of vector measurements. Most of the single frame algorithms described in literature [11], are fully complying with the Wahba’s [8] attitude optimality definition i.e. to find the orthogonal matrix $C$ with determinant +1 that minimizes the following loss function:

$$J(C) = \frac{1}{2} \sum_{i=1}^{N} a_i |b_i - Cr_i|$$  \hspace{1cm} (11)

where, $a_i$ are non-negative weights, $b_i$ and $r_i$ are reference unit vectors measured in spacecraft and inertial frame respectively. Generally, non-negative weights, $a_i$, are normalized to unity but if the weights are chosen to be the inverse of measured error variance i.e. $a_i = \sigma_i^{-2}$ then the solution to Wahba problem is the same as the minimum variance solution.

The attitude estimation problem, as posed by Wahba, is nonlinear in nature irrespective of which attitude parameters are used, and generally, require the use of some iterative procedure to determine the attitude parameters of interest. The total number of iterations required to solve the Wahba problem within desired accuracy depend upon the initial guess of the attitude parameter of interest. Many closed form solutions [13, 4, 14, 15, 5] to Wahba’s problem have been presented in literature but most of them are either in terms of quaternion or Rodrigues parameters. To our knowledge, no closed-form solution to Wahba’s problem exist in terms of any Euler angle set. So it becomes really important to have a good initial guess for Euler angle set to solve the Wahba problem using some iterative methods. In this section, we

---

With the word optimal attitude is usually intended an attitude satisfying the Wahba’s definition of attitude optimality. To our knowledge, only the Euler-q algorithm[12] is based on a different definition of optimality.
present an efficient way to come up with the initial guess for particular Euler angle set of interest using some basic concepts of linear algebra.

Equation (11) represents a linear optimization problem in terms of the elements of the attitude matrix, $C$ subject to nonlinear orthogonality constraint which can be restated as follows:

$$J(x) = \frac{1}{2} |b - Ax|^2$$

$$C^T C = I$$

Where, $b = \{ b^T_1, \ldots, b^T_N \}^T \in \mathbb{R}^{3N}$, $x = \{ C_{11}, C_{12}, C_{13}, \ldots, C_{31}, C_{32}, C_{33} \}^T$ and $A$ is a $3N \times 9$ matrix given by following expression:

$$A = \begin{bmatrix}
    r^T_1 & 0 & 0 & 0 & 0 & 0 & 0 \\
    0 & 0 & 0 & r^T_1 & 0 & 0 & 0 \\
    0 & 0 & 0 & 0 & 0 & r^T_1 & 0 \\
    \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
    r^T_N & 0 & 0 & 0 & 0 & 0 & 0 \\
    0 & 0 & 0 & r^T_N & 0 & 0 & 0 \\
    0 & 0 & 0 & 0 & 0 & 0 & r^T_N \\
\end{bmatrix}$$

(14)

The number of solutions to a linear system of equations $Ax = b$ can be determined by looking at the row echelon form of augmented matrix formed by putting together $A$ and $b$, \[ A : b \].

1. If $b$ has a nonzero element where $A$ has a row consisting entirely of zeros, then the system of equations is inconsistent.

2. If the system is consistent and all the variables are lead variables then there is exactly one solution.

3. If the system is consistent and some of the variables are free variables, then there are an infinite number of solutions.

Now for the attitude determination problem, it can be easily proved that if the vector observations are perfectly known, then for $N > 2$ the row echelon form of augmented matrix \[ A : b \] is given by \[ \begin{bmatrix} I_{9 \times 9} & x \\ O_{(3N-9) \times 9} & 0 \end{bmatrix} \]. Therefore, according to rule 2, the attitude determination problem has a unique solution and, if the solution to Wahba problem exists, then this unique solution is also the solution of Wahba problem.

We state the following theorem to capture the whole idea of above discussion:

**Solution to Wahba’s Problem.** If the solution to Wahba problem exists and matrix $A$ has column rank 9 and $b$ lies in range space of $A$, then the system of equations $Ax = b$ has exactly one solution which satisfy the orthogonal constraint.
So, once we know the attitude matrix \( C \), we can estimate the non-singular Euler angle set using the formulas listed in Ref. [16]. But in real life, the attitude estimation problem is not so simple, and the vector observations, generally body vector measurements, are subject to sensor errors. Due to errors in vector measurements, the vector listing the body reference vectors, \( b \), may not lie in the range space of matrix \( A \), and so we can not even guarantee the existence of the solution to the equation \( Ax = b \). In this case, we can determine the approximate attitude using a deterministic method like TRIAD\[17\] and, later on, one can use the TRIAD solution as an initial guess to find the optimal solution. But the greatest drawbacks of the TRIAD method is that it is applicable only for two vector measurements and a tedious approach is required to combine the solution for the various vector measurements pairs when more than two vector measurements are available. So to overcome this drawback of TRIAD solution, we suggest to find the suboptimal least square solution to equation (12), by discarding the orthogonality constraint given in equation (13):

\[
x = (A^T R^{-1} A)^{-1} A^T R^{-1} b
\]

(15)

Where, \( R \) is the measurement error covariance matrix. It should be noticed that if \( b \), lies in the range space of matrix \( A \) then the least square solution, \( C_{ls} \) will be equivalent to the unique solution listed above. Further, we can pose the Procrustes problem i.e. to find the orthogonal matrix \( \hat{C} \) that is closest to least square solution in the sense of Frobenius norm.

\[
\text{Minimize: } ||\hat{C} - C_{ls}||
\]

(16)

The solution to Procrustes’s problem can be found in ref. [18] and is given by:

\[
\hat{C} = U V^T
\]

(17)

where \( U \) and \( V \) are orthogonal matrices obtained by singular value decomposition of least square solution, \( C_{ls} \).

It should be noticed that even the solution to Procrustes’s problem is not the optimal solution to Wahba’s problem. Therefore, to find the optimal solution in terms of non-singular Euler angle set the concept of small rotation is used. The true solution to the Wahba problem in terms of any non-singular Euler angle sequence can be written as a small rotation to the estimated attitude matrix either by using Procrustes’s problem or the least square method, \( \hat{C} \) i.e.

\[
C = \left( I - \begin{bmatrix} \tilde{\delta} \theta \end{bmatrix} \right) \hat{C}
\]

(18)

Where, \( \begin{bmatrix} \tilde{\delta} \theta \end{bmatrix} \) is the cross product matrix given by following expression:

\[
\begin{bmatrix} \tilde{\delta} \theta \end{bmatrix} = \begin{bmatrix} 0 & -\delta \theta_3 & \delta \theta_2 \\ \delta \theta_3 & 0 & -\delta \theta_1 \\ -\delta \theta_2 & \delta \theta_1 & 0 \end{bmatrix}
\]

(19)

\*To avoid any confusion, \( \hat{C} \) will be used to denote the initial guess for attitude matrix
Now, modelling the sensor errors as Gaussian white noise and making use of the fact that \( b_i = Cr_i \), we can write:
\[
\tilde{b}_i = Cr_i + \nu_i
\]  
(20)

where, \( \tilde{b}_i \) represents the measured vector observation in the body reference frame. Further, substitution of equation (18) in equation (20) yields the following expression:
\[
\tilde{b}_i = \left( I - \begin{bmatrix} \hat{\delta}\theta \end{bmatrix} \right) \hat{C}r_i + \nu_i
\]  
(21)

After some algebraic manipulations, we can rewrite equation (21) as:
\[
\tilde{b}_i - \hat{b}_i = \begin{bmatrix} \tilde{b}_i \end{bmatrix} \delta\theta + \nu_i
\]  
(22)

where, \( \tilde{b} = \hat{C}r_i \). Now the set of small rotation angles \( \delta\theta \) can be estimated from equation (22) using Gaussian Least squares:

So the whole Euler angle estimation algorithm can be summarized as follows:

1. Given vector measurements \( b_i \) and \( r_i \) find which euler angle set is non-singular.
2. Find the least square solution for attitude matrix, \( C \) and call it \( C_{ls} \).
3. Find the closest orthogonal matrix, \( \hat{C} \) to least square solution \( C_{ls} \) by solving Procrustes problem.
4. Find the estimate for non-singular Euler angle set and call it \( \hat{\theta}_1 \).
5. set \( i = 1 \).
6. find \( \hat{\theta}_{i+1} = \hat{\theta}_i + \delta\theta_i \) using equation (22).
7. Repeat step 6 till desired accuracy is obtained.

The above mentioned procedure permits the computation of optimal Euler angle set to arbitrarily high accuracy. The procedure to find the initial guess for Euler angle set is of practical interest and very useful in reducing the total number of iterations required to find the optimal solution to the Wahba problem in terms of particular Euler angle set. Further, we mention that this procedure can be used to start any nonlinear estimation algorithm like the “Extended Kalman Filter” to estimate the Euler angle set in real time.

6 Error Analysis

In this section, We determine a relationship between the attitude error and the measurement noise using the computed attitude. This is accomplished by using the
Wahba’s loss function:
\[ J = \frac{1}{2} \sum_{i=1}^{n} (\tilde{b}_i - \hat{b}_i)^T R_i (\tilde{b}_i - \hat{b}_i) \]  
\hspace{1cm} (23)

where, \( n \) is the total number of vector measurement available. According to the Gauss Markov equation [19] the error attitude can be computed as
\[ \delta \theta = (H^T R^{-1} H) H^T R^{-1} \nu \]  
\hspace{1cm} (24)

where,
\[ H = \begin{bmatrix}
-\tilde{b}_1 \\
-\tilde{b}_2 \\
\vdots \\
-\tilde{b}_n
\end{bmatrix} \]
\[ R = \begin{bmatrix}
R_1 & O & \cdots & O \\
O & R_2 & \cdots & O \\
\vdots & \vdots & \ddots & \vdots \\
O & O & \cdots & R_n
\end{bmatrix} \]  
\hspace{1cm} (25)

We recognize that \( H^T R^{-1} H \) is the attitude error covariance matrix \( P \) derived from the least square formulation. Therefore, equation (24) can be re-written as
\[ \delta \theta = P H^T R^{-1} \nu \]  
\hspace{1cm} (26)

Now, let us consider the residual covariance matrix \( \Gamma_k \)
\[ \Gamma_k = \mathbb{E}[(\tilde{b}_k - \hat{b}_k)(\tilde{b}_k - \hat{b}_k)^T] \]  
\hspace{1cm} (27)

Further, substitution of equation (22) in equation (27) leads to following expression:
\[ \Gamma_k = \mathbb{E}(\nu_k \nu_k^T + [\tilde{b}_k] \delta \theta \nu_k^T + \nu_k \delta \theta^T [\tilde{b}_k]^T + [\tilde{b}_k] \delta \theta \delta \theta^T [\tilde{b}_k]^T) \]  
\hspace{1cm} (28)

Next, since the vector measurement errors are uncorrelated, we have
\[ \mathbb{E}(\delta \theta \nu_k^T) = P [\tilde{b}_k]^T \]  
\hspace{1cm} (29)
\[ \mathbb{E}(\nu_k \delta \theta^T) = [\tilde{b}_k]^T P \]  
\hspace{1cm} (30)

Finally, substitution of equations (29) and (30) in equation (28) and using the fact that \( [\tilde{b}_k] \) is a skew symmetric matrix leads to the following expression for \( \Gamma_k \)
\[ \Gamma_k = R_k - [\tilde{b}_k] P [\tilde{b}_k]^T \]  
\hspace{1cm} (31)
The matrix $\Gamma_k$ can be computed independently by following recursive expression:

$$
\Gamma_i(k+1) = \Gamma_i(k) + \frac{1}{k+1} \left\{ \frac{k}{k+1} [e_i(k+1) - \bar{e}_i(k)] [e_i(k+1) - \bar{e}_i(k)]^T - \Gamma_i(k) \right\}
$$

(32)

where

$$
\bar{e}_i(k+1) = \bar{e}_i(k) + \frac{1}{k+1} [e_i(k+1) - \bar{e}_i(k)]
$$

(33)

where $e_i = \tilde{b} - \hat{b}$ is the residual error and $\bar{e}_i$ is the mean of residual error. Equation (31) can be used to check the validity of the attitude determination algorithm mentioned in last section. It should be made sure that, the error covariance is inline with the projected random error magnitude and the left hand side of equation (31) matches well with the right hand side.

7 Numerical Simulation

In this section, we test the algorithm, developed in this paper, by simulating star camera images. The spacecraft body frame star vectors and the reference frame star vectors are simulated by using the J-2000 star catalog with stars of visual magnitude brighter than $M_v \sim 6.4$. The FOV of the star camera is assumed to be $8^6 \times 8^6$ and the true spacecraft body frame vectors are corrupted by centrioding error of $17\mu$ radian. The angular motion of the spacecraft, for simulation purposes is established by prescribing an exact nominal Euler 3-2-1 angle motion.

$$
\theta_1(t) = \sin(t/4), \theta_2(t) = \frac{\pi}{2} \sin(t/5), \theta_3(t) = \cos(t/5)
$$

(34)

Figure 3 shows the plot of the true 3-2-1, Euler angles with time. It should be noticed that for the choice of angular motions, the 3-2-1 Euler angle set can not used to estimate the spacecraft attitude at each time. Therefore, whenever 3-2-1 Euler angle set approaches singularity we switch to 3-1-3 Euler angle set to compute the spacecraft attitude. Initially, the least square solution given by equation (15) is used to compute the non-singular Euler angle set, 3-2-1, in this case. The method of sequential least squares [19] and small rotation, as described in previous section, is used to find the spacecraft attitude at subsequent times. Figure 4 shows the plot of the attitude error** angle with time. From this figure, it is clear that the procedure listed in previous section works well for the attitude estimation in terms of non-singular Euler angle set.

**Attitude Error is defined as the principal rotation angle corresponding to error attitude matrix i.e. $\cos^{-1}(\frac{1}{2} Tr(C_{true}C_{estimated}^T - I))$

8 Conclusion

An efficient algorithm based upon switching between different Euler angle sets is presented to avoid the geometric singularity associated with different Euler angle sets. The switching algorithm presented in this paper is based upon some well known observations regarding Euler angle sets and is of practical significance mostly in the field of robotics and spacecraft attitude control. In addition, an efficient algorithm is presented to find the optimal solution to the Wahba problem in terms of non-singular Euler angle set. The algorithm presented in paper is based upon some basic algebraic concepts and can be used as a starting method for the nonlinear attitude estimation algorithms like the “Extended Kalman Filter” for real time applications. However, the switching between different Euler angle set in Kalman filter to avoid the singularity is still an issue. Finally, we mention that although we present a mechanism to avoid the singularity in the Euler angle set but, more work is required to make this procedure attractive for the spacecraft attitude estimation problem.
